

The Stellar Disintegration Zone

Jeffrey J. Wolynski
September 29, 2018
Rockledge, FL 32955

Abstract: The stellar disintegration zone is the area that separates hot Jupiters from their more evolved and evolving counterparts. It shows that hot Jupiters lose their thick helium/hydrogen atmospheres faster if they orbit close to a much hotter host star, which is predicted by the General Theory of Stellar Metamorphosis. The SDZ on this graph is between 5-9 Earth Radii, with a period shorter than 10 days. As well, the SDZ's can be different for different stars, this graph is only a generalization. Data is taken from various telescopes including the Kepler, and 2,504 evolving/dead stars are on the graph. The periods of the dead/evolving stars on the graph do not include the ones beyond 50 days, and objects beyond a radius of 23 Earths. Data for the points on the graph is included, as well as the objects' names.

What this graph shows us in the orange box is that there really is a gap in stellar evolution. This is due to atmospheric escape as a hot Jupiter (already very evolved star) does not have a large enough gravitational field to hold on to its helium and hydrogen. We should expect this gap to become more pronounced as the data comes in from the Transiting Exoplanet Survey Satellite (TESS). It is suggested for astronomers to realize that not all stars pass through this gap, the only purpose of this paper is to show quite clearly that Hot Jupiters in fact do lose

their mass due to physical changes (changing orbits/adoption per the adoption principle of stellar metamorphosis) that were not predicted by Big Bang or the Nebular Hypothesis. It also shows that the rate at which a star evolves is probably sped up significantly the closer to the SDZ it gets. So Jupiters and other older stars that have lots of helium/hydrogen can evolve on slower timescales the further they are from the SDZ. What is most likely true is that since orbits are really tight for the Hot Jupiters, they have a higher possibility of becoming small moons, as the amount of material that differentiates and forms the core is reduced significantly. What this means is that if we observe a small, differentiated moon, then it at one point passed through the SDZ of another star. As well, the SDZ's of younger hotter stars are not all the same, some are bigger than others, as this graph is a generalization. The SDZ of a blue giant would be huge, and of a red dwarf it would be really small and close in.

Puffed out Jupiters or really diffuse gas giants probably escaped another SDZ at one point, given they have moved out of that zone. So what this means is that they could both still have moons, or even adopted them while they were in a SDZ. More work will need to be done, but for sure, SDZ's do exist and they speed up a star's evolution, and change the host's atmosphere considerably, as predicted by stellar metamorphosis and outlined in the atmospheric thinning principle.
